**ESTIMATING QUARTERLY REAL OUTPUT FOR CARICOM COUNTRIES
USING THE LISMAN-SANDEE TEMPORAL DISAGGREGATION METHOD**

By

Jean Marie Cayemitte

ABSTRACT

The unavailability of short term economic data for CARICOM countries have often made it difficult to determine exogenous shocks and forecast their impact. Consequently, this paper develops quarterly real Gross Domestic Product (GDP) estimates using the temporal disaggregation method of Lisman and Sandee (1964). The plausibility of these quarterly estimates is checked by considering two simple regression models related to money supply and real income. The results indicate that these models give parameters estimates that are in line with economic theory.

1. Introduction

Caribbean countries often find themselves in very precarious economic situations, influenced by their limited size, vulnerability to natural disasters and heavy dependence on the developed economies like the United States and Europe for trade and finance. As Craigwell and Maurin (2007) have argued, one way to control some of the effects from these constraints is for Governments in the region to determine and anticipate the business cycles of these economies, which comprise alternating periods of economic upturns and declines, and which is primarily measured by gross domestic product (GDP) fluctuations. As a result, economic surveys of the region should concentrate on providing information to follow closely short-term economic fluctuations. Unfortunately, and disturbingly, particularly since, a *priori* reasoning would suggest, that economic fluctuations are likely to be more substantial and persistent in developing countries than in industrialized economies, most of the countries in the Caribbean seemed to have overlooked these short-term concerns as their economic surveys often focus on typical problems pertaining to long-term tendencies and repercussions of national output. This is exemplified by the fact most of the information in these economic surveys utilised annual national accounts, which is totally inadequate to identify business cycles and to anticipate their impact.

Given the above, Caribbean territories must follow the lead of the developed countries and the more advanced developing economies and create statistical methodologies to enable them to provide indicators to build quarterly national accounts aimed at estimating and forecasting economic fluctuations in the short-term. Some islands such as Barbados and Trinidad and Tobago have already started this process of creating quarterly data, but the others are still in the preliminary phase of putting together the necessary resources. Bringing all the countries on a level playground cannot be overemphasised, especially with the advent of the Caribbean Single Market and Economy where the link between the islands is envisaged to get much closer with coordinated macroeconomic policies.

In light of the budgetary constraints faced by Caribbean governments in this globalised world, it is very unlikely that they will be able to generate quarterly national accounts from first principles such as surveys in the near future. A least costly and practical alternative approach that has been

used extensively worldwide (see Eurostat (1999) for a survey) is to develop quarterly data from the already existing annual data using various statistical methods. It is this procedure that is adopted in this paper to develop quarterly output data for 14 Caribbean countries over the period 1971 to 2004. The method employed in this paper is based on the work of Lisman and Sandee (1964). More approaches will be undertaken in due course.

After the introduction the paper reviews the methodologies usually used to develop quarterly high frequency data from annual low frequency data. Then, a discussion of the Caribbean literature that utilised the above approaches is presented. In the third section, the Lisman and Sandee (1964) method is applied to real output data from 14 Caribbean countries. In the next section, simple models are estimated with the quarterly estimates to evaluate their plausibility in explaining economic phenomena. Finally, conclusions are made.

2. A Short Review of Temporal Disaggregation Methods

Temporal disaggregation methods are mathematical and statistical procedures that allow low frequency (annual) data to be decomposed into high frequency (quarterly) data. Eurostat (1999, pp.148) distinguished between three types of temporal disaggregation methods: (i) methods that do not involve the utilisation of related indicators; (ii) methods that make use of related series and (iii) extrapolation methods. Given this paper multi-country approach and the need to keep it focussed, only the first set of methods are analysed here; the readers are referred to the Eurostat article mentioned above, Di Fonzo (2003a,b) and Proietti (2004) for a review of the other two approaches. These latter procedures will be undertaken in another paper planned by this author.

Quarterly estimates are obtained from the methods that do not involve the use of indicators by either providing a sufficiently smoothing quarterly path coherent with the temporal aggregate constraints or by using time series models. They are particularly suited to cases where there are serious gaps in the data and only annual series are available.

2.1 Smoothing Methods

These methods typically assume that the unknown quarterly trend can be written as a function of time, either given a priori or to be chosen within a larger class, such that the necessary condition of satisfying aggregate constraints and the desirable condition of smoothness are both met. In this category there are several methods: “Dividing by 4”(see Eurostat (1999)), Lisman and Sandee (1964), Boot, Feibes and Lisman (1967) and Jacob (1994). These are discussed briefly for the case of a flow variable distribution to coincide with the distribution of real gross domestic output (GDP).

2.1.1 Method of “Dividing by 4” and Linear Interpolation

In the case of a flow, the disaggregation matrix should be written as: $H = \frac{1}{4} \cdot C$, where C is an $(n \times 4n)$ aggregated matrix defined as

$$C = \begin{pmatrix} 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & . & . & . & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & . & . & . & 0 & 0 & 0 & 0 \\ . & . & . & . & . & . & . & . & . & . & . & . & . & . & . \\ . & . & . & . & . & . & . & . & . & . & . & . & . & . & . \\ . & . & . & . & . & . & . & . & . & . & . & . & . & . & . \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & . & . & . & 1 & 1 & 1 & 1 \end{pmatrix}$$

However, with this approach, after disaggregation, $4(T-1)$ observations remain, and the disaggregation matrix is expressed as follows: $H = A + \frac{1}{4} \cdot BD$ where $A = [C'_{T-1} \ O_{4(T-1)}]$ with $O_{4(T-1)}$ being a $4(T-1) \times 1$ null vector,

$$B = \begin{bmatrix} \bar{B} & 0 & \dots & 0 \\ 0 & & & \\ \vdots & \ddots & & \vdots \\ 0 & \dots & 0 & \bar{B} \end{bmatrix} \text{ is a } 4(T-1) \times 4(T-1) \text{ matrix with}$$

$$\bar{B} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 3 \end{bmatrix} \text{ and } D = \begin{bmatrix} \hat{D} & 0 & \dots & 0 \\ 0 & & & \\ \vdots & \ddots & & \vdots \\ 0 & \dots & 0 & \hat{D} \end{bmatrix} \text{ is a } 4(T-1) \times T \text{ matrix with}$$

$$\hat{D} = \begin{bmatrix} -1 & 1 \\ -1 & 1 \\ -1 & 1 \\ -1 & 1 \end{bmatrix}.$$

2.1.2 The Lisman and Sandee Procedure

In the case of the “Dividing by 4” method there is a discontinuity in the disaggregated times series at the beginning of every year. To avoid this problem, Lisman and Sandee (1964) used a weighted mean of the quarterly values of the years $\alpha-1$, α , $\alpha+1$. This procedure includes two steps. Firstly, four quarterly values from the known annual value A_α is built. Hence,

$$\Psi_{1\alpha} = \Psi_{2\alpha} = \Psi_{3\alpha} = \Psi_{4\alpha} = \frac{1}{4} A_\alpha = \Psi_\alpha$$

Secondly, a system of weighted means from values $\Psi_{i,\alpha-1}$, $\Psi_{i,\alpha}$ and $\Psi_{i,\alpha+1}$ is derived in order to estimate the quarterly time series $X_{i,\alpha}$ in quarter i of current year α . This system is expressed as:

$$\begin{aligned} X_{1,\alpha} &= 0.291.\Psi_{\alpha-1} + 0.793.\Psi_\alpha - 0.084.\Psi_{\alpha+1} \\ X_{2,\alpha} &= -0.041.\Psi_{\alpha-1} + 1.207.\Psi_\alpha - 0.166.\Psi_{\alpha+1} \\ X_{3,\alpha} &= -0.166.\Psi_{\alpha-1} + 1.207.\Psi_\alpha - 0.041.\Psi_{\alpha+1} \\ X_{4,\alpha} &= -0.084.\Psi_{\alpha-1} + 0.793.\Psi_\alpha - 0.291.\Psi_{\alpha+1} \end{aligned}$$

The inconvenient of this method is that values for years α and $\alpha+1$ must be forecast.

2.1.3 Method of Boot, Feibes and Lisman (1967)

Boot, Feibes and Lisman resolved the inconvenience in the previous procedure by treating the problem of estimating quarterly series consistent with a given annual series as a solution of a constrained minimization problem. They used several objective functions but the two versions currently in use are the first difference and the second difference. In mathematical terms, the method can be expressed as:

$$\min_{(X_1, \dots, X_{4\alpha})} \sum_{j=2}^{4\alpha} [X_j - X_{j-1}]^2$$

subject to the constraint that: $\sum_{j=4y-3}^{4y} X_j = A_y$, $y \in \{1, \dots, \alpha\}$ where X is the quarterly time series to be estimated. The Boot, Feibes and Lisman first difference estimates are the solution in X of the following linear system

$$\begin{bmatrix} B & C' \\ C & O \end{bmatrix} \cdot \begin{bmatrix} X \\ \lambda \end{bmatrix} = \begin{bmatrix} O \\ A_\alpha \end{bmatrix}$$

where λ is a $n \times 1$ vector of Lagrange multipliers, C is as defined above, $B = 2M' \times M$

$$= \begin{bmatrix} 2 & -2 & 0 & 0 & 0 & \dots & 0 & 0 & 0 \\ -2 & 4 & -2 & 0 & 0 & \dots & 0 & 0 & 0 \\ 0 & -2 & 4 & -2 & 0 & \dots & 0 & 0 & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & 0 & 0 & 0 & \dots & -2 & 4 & -2 \\ 0 & 0 & 0 & 0 & 0 & \dots & 0 & -2 & 2 \end{bmatrix}$$

and $M = \begin{bmatrix} -1 & 1 & 0 & \dots & \dots & 0 & 0 \\ 0 & -1 & 1 & \dots & \dots & 0 & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & 0 & \dots & \dots & -1 & 1 \end{bmatrix}$ is $(4\alpha-1) \times 4\alpha$ matrix which transforms the X into

their differences.

2.1.4 The Procedure of Jacobs (1994)

This method elaborates on Boot, Feibes and Lisman (1967) by providing an explicit expression for the matrix that converts annual totals into quarterly data. An algorithm, based on the matrix, is developed and it computes the quarterly series in linear time and memory. Jacobs (1964) also found a close connection between the Boot, Feibes and Lisman approach and Generalised Least Squares.

2.2 Time Series Models

The time series procedures are the most recent of the temporal disaggregation methods. They seek to incorporate all the information on the dynamics contained in the historical time series in the temporal disaggregation models. These models follow closely the Autoregressive Integrated Moving Average (ARIMA) processes. Given the time series nature of these ARIMA processes, the time series models of temporal disaggregation have the advantage that they can be applied in cases where there is a lack of information on related indicators. The models discussed below falls into this category, that is, the methods of Al-Osh (1989) and Wei and Stram (1990). However, note that quarterly series can also be estimated by including information from quarterly related indicators into the ARIMA process, which guides the infra-annual path.

2.2.1 Method of Wei and Stram

Taking into account the close relationship between the ARIMA model and its autocovariance structure, Wei and Stram (1990) used the available autocovariances of the aggregate model to estimate the autocovariance structure of the unknown series. Formally, let $Y_{4(\alpha-1)+\phi}$ be the unknown value of the aggregate Y^* for the quarter ϕ of year α and Y_α , $\alpha=1, \dots, n$, the corresponding known annual value. Then the relation between Y^* and Y_α is given by:

$$Y_\alpha = \sum_{\phi=1}^4 Y_{4(\alpha-1)+\phi} \quad \alpha=1, \dots, n$$

or

$$Y_\alpha = \frac{1}{4} \sum_{\phi=1}^4 Y_{4(\alpha-1)+\phi} \quad \alpha=1, \dots, n$$

Now, consider the stationary series: $W_\alpha = (1-L)^d Y^*_\alpha$ and $U_\alpha = (1-L)^d Y_\alpha$ obtained by differentiating the basic and the aggregated series, respectively. A result by Barcellan and Di Fonzo (1993) states that the relationship between the covariances of W_α and Y_α permits the use of a generalized least squares procedure that is able to supply estimates which fulfil the aggregation constraint:

$$Y^* = \begin{bmatrix} \Delta_n^d \\ 0 \quad I_d \otimes c' \end{bmatrix}^{-1} \begin{bmatrix} V_w (C_d)' V_u^{-1} \Delta_n^d \\ 0 \quad I_d \end{bmatrix} Y$$

where V_u and V_w are the variance-covariance matrix obtained from the relation between the autocovariances of the stationary aggregated and disaggregated models, C_d is the matrix which contains the information provided by the aggregate model, \otimes is the Kronecker product and $c = (1, 1 \dots 1)'$ represents the flow variable distribution. In practice, V_u and V_w are usually not known and have to be estimated from available data. Although the estimation of V_u can be easily computed from the aggregated model parameter estimates, the process for V_w is not as straightforward. Moreover, the Wei and Stram (1990) procedure assumes a one to one relationship between the autocovariances of the aggregated and disaggregated models, which only holds under special conditions (see Eurostats, 1999).

2.2.2 The Method of Al-Osh

This method uses a state space representation of the ARIMA model to describe the unknown series under the temporal aggregation constraint. The estimated state vectors and the corresponding covariance matrices are obtained from the Kalman filter with reference to the state space representation.

3. A Brief Review of Temporal Disaggregation Studies in The Caribbean

As discussed in the previous section, there are several methods that convert an aggregated low frequency series into a disaggregated high frequency series. This section looks at the studies that have used these procedures on the GDP data of Caribbean countries.

Table 1: A Tabular Survey of Temporal Disaggregation GDP Studies in the Caribbean

Authors	Countries	Variables	Samples	Methods
Prescod (1986)	Barbados	Real GDP by sector	1974-1985	Lisman-Sandee (1964)
Forde, Singh and Coker (1987)	Trinidad and Tobago	Real GDP by sector	1982-1997	Extrapolation
Nicholls, Forde and Coker (1995)	Trinidad and Tobago	Real GDP	1983-1993	Lisman-Sandee (1964)
Lewis (1997)	Barbados	Real GDP by sector	1974-1995	Extrapolation
Nicholls (2002)	Belize	Real GDP	1990-2001	Chow-Lin (1971)
Allen (2002)	Jamaica	Real GDP	1981-1998	Lisman-Sandee (1964)
Serju (2004)	Jamaica	Real GDP based expenditure	1991-2002	State Space
Perry (2006)	Tobago	Nominal GDP	1997-2004	Chow-Lin (1971)

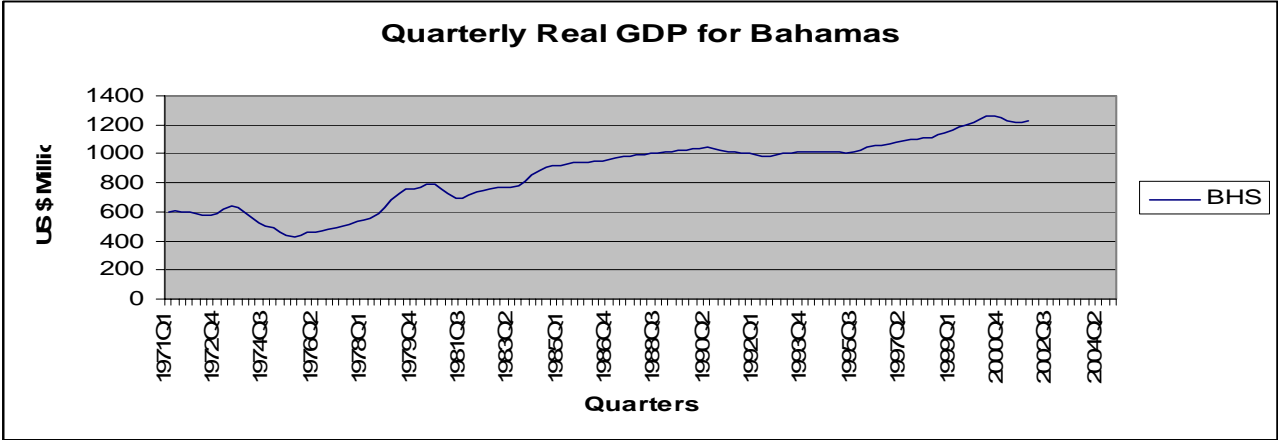

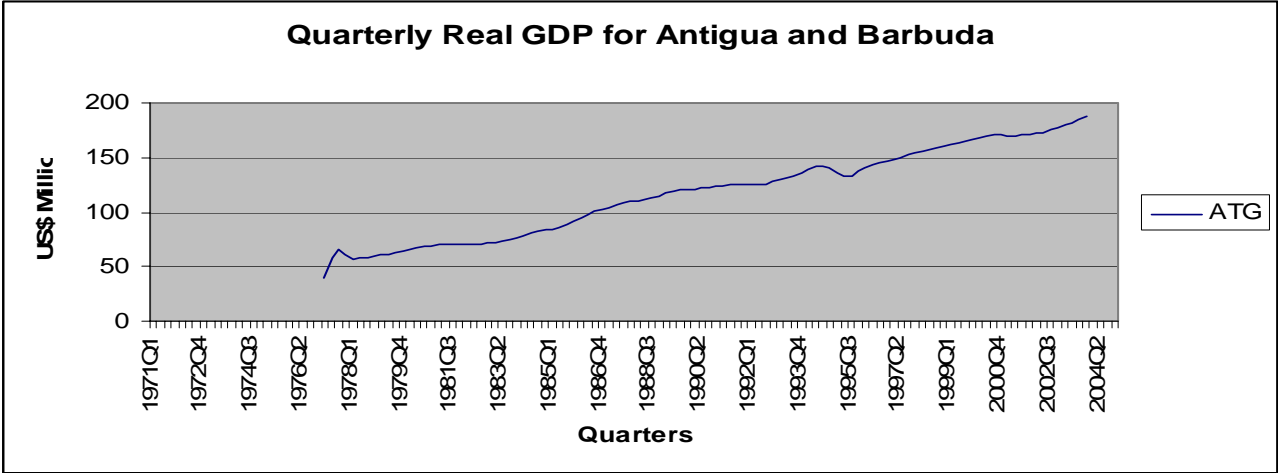

From Table 1 it is observed that these methods have mainly been conducted on the GDP data of the more developed Caribbean countries. Indeed, with the exception of Nicholls (2002) on Belize and Perry (2006) on Tobago all the other studies utilized GDP data from Barbados, Trinidad and Tobago or Jamaica. Furthermore, the table revealed that the most common procedures employed have been the Lisman-Sandee and Extrapolation, presumably because these are relatively easy to compute. Finally, most of the research has been done on GDP by sector as apposed to overall GDP.

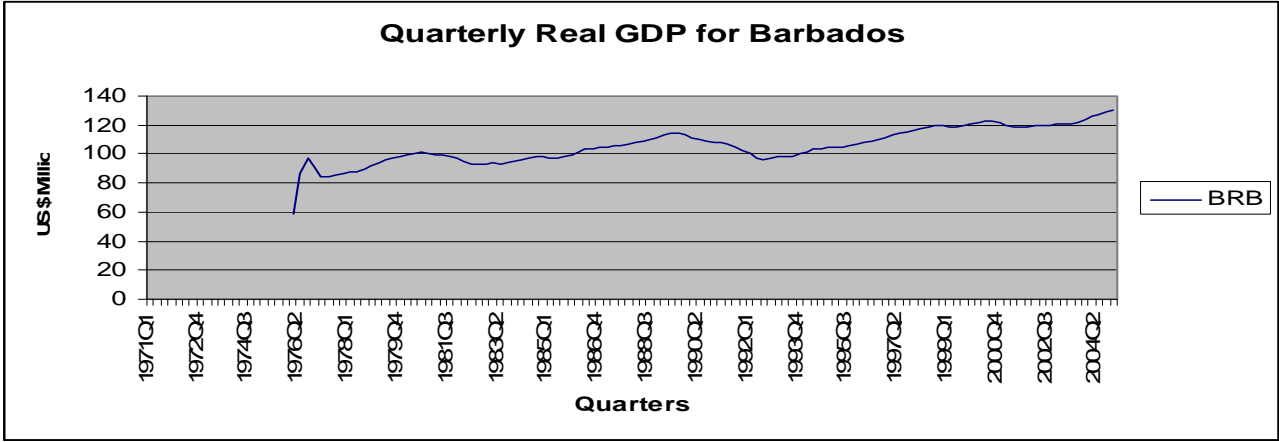

4. Estimates Of Quarterly Real GDP Using the Lisman and Sandee Method

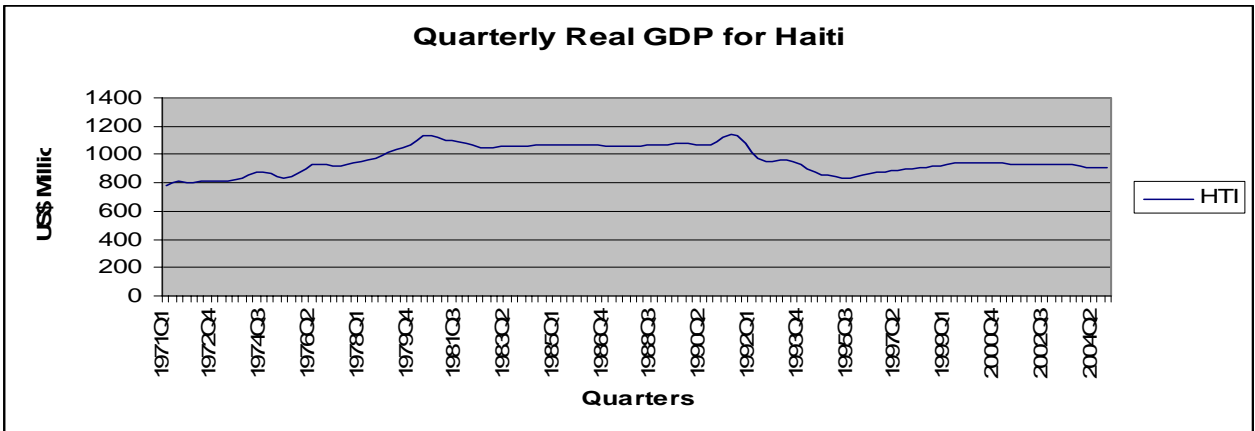

Taking into account the data constraint of the majority of the CARICOM countries, this section estimates the quarterly real GDP from annual data for these countries using the Lisman-Sandee (1964) approach. The results obtained (see Figure 1 and the Appendix) show that the quarterly estimates of real GDP has an increasing trend for all the CARICOM countries, except Suriname and Haiti whose fluctuations are less persistent and Guyana whose estimated quarterly real GDP recorded a downward trend from the second quarter of 1981 to the third quarter of 1990. All the

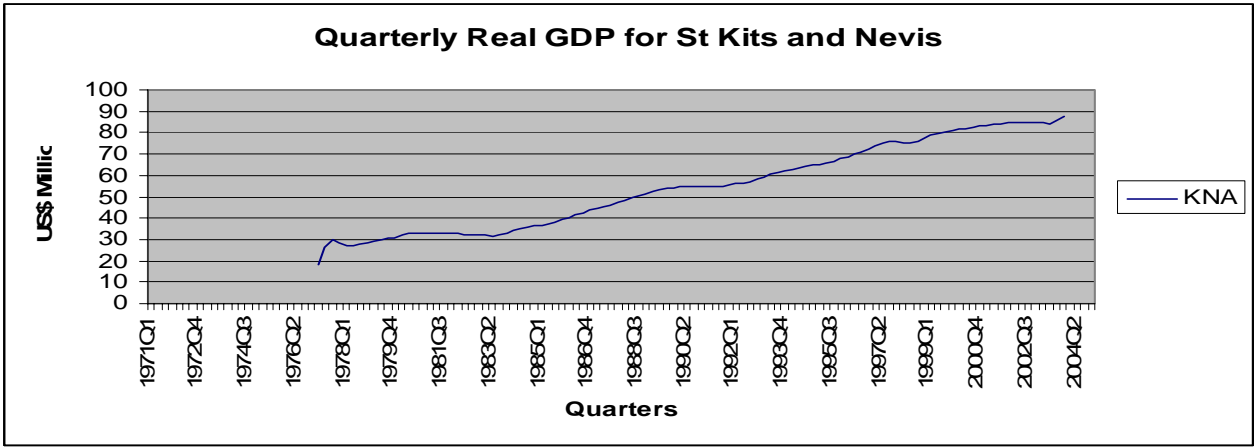

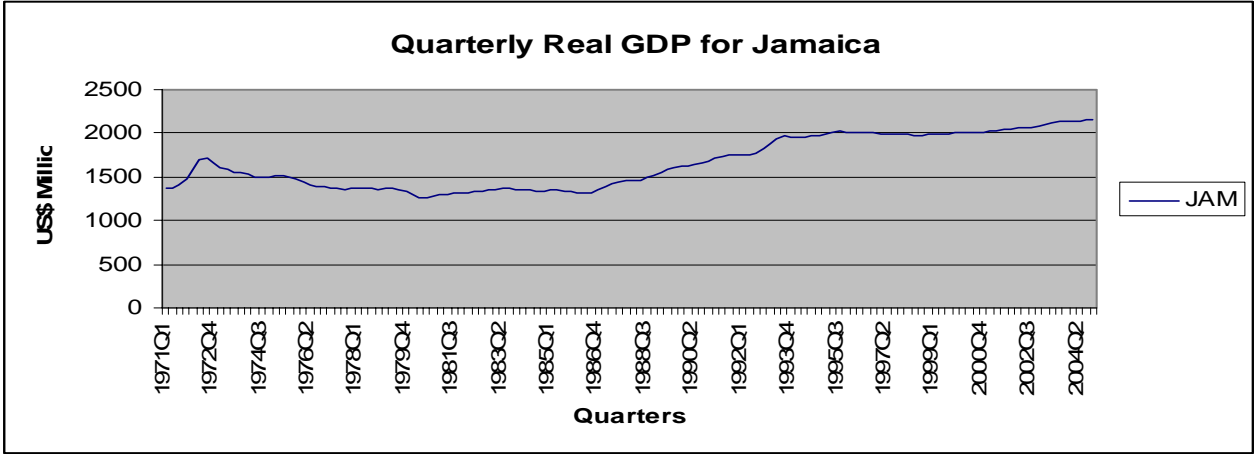

data in this paper was taken from the Annual Statistical Digest of the Central Bank of Barbados, International Financial Statistics of the International Monetary Fund and the World Bank's World Development Indicators Online. Computations were done using the RATS software programme.

Quarterly Real GDP for St Vincent and The Grenadines

Quarterly Real GDP for Suriname

Quarterly Real GDP for Trinidad and Tobago

5. Robustness of the Quarterly Real GDP Estimates

As mentioned in the introduction of this paper, the real GDP estimates derived above are intended to serve as a proxy for quarterly real GDP until steps can be put in place to calculate the official series. It is therefore necessary that these estimates do not distort underlying economic relationship. This can be checked by estimating standard economic relationships. As such, two simple regressions are run. The first is an income determination equation:

$$CARINCOM_t = \alpha + \beta * USINCOM_t + \varepsilon_t \quad (1)$$

where t represents the number of quarters; $CARINCOM$ is real income for the respective CARICOM countries; $USINCOM$ is the income of the United States and ε is the error term which is assumed to have normal properties. The second equation to be estimated is a money demand function where income is one of the explanatory factors, that is,

$$MON_t = \gamma + \delta * CARINCOM_t + \zeta * IR_t + \eta * CPI_t + \mu_t \quad (2)$$

where t and $CARICOM$ are defined as above; MON represents money demand; IR is the interest rate; CPI is the consumers price index and μ is an error term with classical properties assumed.

According to the results of Tables 2 the quarterly real income for the United States positively and significantly influences quarterly real GDP of all CARICOM countries, except Suriname, which has the correct sign but is statistically insignificant. This model explains reasonably well the amount of variability in the data, that is, excluding the low R^2 for Guyana, Haiti and Suriname, the other countries show an R^2 of about 50% with a high of 98% for Antigua and Barbuda. Likewise for the money demand equation (Table 3), the model explains a significant amount of variation in the data (R^2 ranging from 83% to 99%); the income variable is positive and significant for all countries except Guyana. In addition, the price and interest rate variables are also as expected for the majority of the countries. These results suggest that the quarterly income estimates may be a reasonable proxy for the actual series.

Table 2: Results of Real Income Equation

Countries (Sample=N)	USINCOM	R²
Antigua and Barbuda (N=108)	0.752 (69.804)	0.979
The Bahamas (N=124)	0.424 (28.371)	0.868
Barbados (N=116)	0.193 (18.656)	0.753
Belize (N=132)	0.794 (49.541)	0.950
Dominica (N=108)	0.498 (33.333)	0.913
Grenada (N=108)	0.655 (52.080)	0.962
Guyana (N=136)	0.067 (3.571)	0.087
Haiti (N=136)	0.026 (2.141)	0.033
Jamaica (N=136)	0.190 (12.711)	0.545
St Kits and Nevis (N=108)	0.786 (62.012)	0.974
St Lucia (N=96)	0.897 (33.838)	0.924
St Vincent and The Grenadines (N=136)	0.528 (45.577)	0.939
Suriname (N=120)	0.022 (1.342)	0.015
Trinidad and Tobago (N=136)	0.211 (11.676)	0.504

Table 3: Results of Money Demand Equation

Countries (Sample=N)	CARINCOM	IR	CPI	R²
Antigua and Barbuda (N=14)	2.138 (2.013)	0.000 (0.000)	-0.130 (-3.915)	0.898
The Bahamas (N=123)	0.885 (8.841)	-0.180 (-7.495)	0.939 (14.341)	0.972
Barbados (N=111)	1.278 (7.139)	-0.234 (11.838)	1.270 (24.874)	0.973
Belize (N=78)	1.399 (13.783)	0.386 (7.596)	1.402 (3.781)	0.974
Dominica (N=96)	2.429 (5.775)	-9.046 (-2.459)	0.061 (0.128)	0.938
Grenada (N=90)	1.597 (8.480)	2.392 (2.709)	0.325 (1.242)	0.990
Guyana (N=55)	-0.432 (-1.002)	-0.138 (-2.634)	1.789 (7.514)	0.945
Haiti (N=32)	1.547 (2.172)	-0.014 (-0.488)	0.982 (28.052)	0.966
Jamaica (N=136)	1.249 (10.878)	-0.032 (-1.070)	1.012 (64.469)	0.997
St Kits and Nevis (N=81)	2.155 (6.395)	0.000 (0.000)	-0.226 (-0.371)	0.832
St Lucia (N=96)	1.031 (8.808)	1.135 (2.844)	1.231 (6.605)	0.975
St Vincent and The Grenadines (N=100)	0.853 (2.487)	-0.709 (-2.455)	2.254 (5.207)	0.913
Suriname (N=55)	4.591 (7.950)	-0.009 (-0.121)	0.783 (27.279)	0.992
Trinidad and Tobago (N=136)	0.812 (7.063)	-0.381 (-7.736)	1.149 (34.203)	0.984

6. Conclusion

Given that it is important for Caribbean countries to control output fluctuations in the short term and forecast business cycles, this paper employs a temporal disaggregation method to compute quarterly real output data. Based on the Lisman and Sandee (1964) approach, the results obtained for the most of CARICOM countries revealed that there is an increasing trend throughout the period 1971-2004. In addition, to check the plausibility of the quarterly real GDP estimates two simple regression models related to money demand and real income are run. These results show that the coefficients of both models have the expected sign and significance suggested by economic theory. As this study covers 14 CARICOM countries, with different data constraints, the temporal disaggregation method chosen does not involve the use of related series. Future work will involve estimating quarterly real GDP using methodologies that involve related series.
